ABSTRACT

Risk variants of the fat-mass and obesity-associated (*FTO*) gene have been associated with increased obesity. However, the evidence for associations between *FTO* genotype and macronutrients intake has not been reviewed systematically. Our aim was to evaluate potential associations between *FTO* genotype and intakes of total energy, fat, carbohydrate and protein. We undertook a systematic literature search in Medline, Scopus, EMBASE and Cochrane of associations between macronutrients intake and *FTO* genotype in adults. Beta coefficients and confidence intervals were used for per-allele comparisons. Random-effects models assessed the pooled effect sizes. We identified 56 eligible studies reporting on 213 173 adults. For each copy of the *FTO* risk allele, individuals reported 6.46 kcal/day (95% CI: 10.76, 2.16) lower total energy intake ($P=0.003$). Total fat ($P=0.028$) and protein ($P=0.006$), but not carbohydrate intakes, were higher in those carrying the *FTO* risk allele. After adjustment for body weight, total energy intakes remained significantly lower in individuals with the *FTO* risk genotype ($P=0.028$). The *FTO* risk allele is associated with a lower reported total energy intake and with altered patterns of macronutrients intake. Although significant, these differences are small and further research is needed to determine whether the associations are independent of dietary misreporting.

INTRODUCTION

Obesity is a major health problem worldwide with 16.6 % of European adults¹ and 9.3% of adults worldwide now obese². Obesity is due to a positive energy balance sustained over substantial time and is associated with carriage of risk variants in genes, some of which appear to influence appetite regulation³. Genome-wide association studies (GWAS) have indicated that single nucleotide polymorphisms (SNPs) in the fat mass and obesity-associated gene (*FTO*) are strongly associated with increased body mass index (BMI) and adiposity across age groups⁴⁻⁶. Individuals homozygous for the risk allele of *FTO* (rs9939609) have a 1.7-fold increased risk of being obese compared with subjects homozygous for the lower-risk allele⁴.

Some evidence suggests that the obesity risk attributable to polymorphisms in *FTO* could be modified by dietary intakes. In particular, limiting saturated fat intake seems to be associated with a lower risk of weight gain in individuals with the *FTO* risk allele^{7,8}. Although the mechanism responsible for the link between carriage of the *FTO* risk allele, dietary intake and BMI remains unclear, evidence suggests that the *FTO* gene may regulate energy homeostasis⁹. *FTO* genotype appears to determine neural responses to circulating concentrations of the hunger hormone ghrelin¹⁰, which may lead to increased energy intake in those carrying the risk allele. A recent GWAS has found a robust association between *FTO* genotype and protein intake¹¹ but associations between *FTO* genotype and intakes of macronutrients^{12,13} and of total energy¹⁴⁻¹⁶ are less consistent¹⁷. Indeed, two recent meta-analyses have indicated that the *FTO* risk allele is associated with lower total energy intake in adults¹⁸. A critical and systematic analysis of the evidence on the associations between *FTO* genotype and intakes of the total energy and macronutrients is lacking.

This systematic review and meta-analysis aimed to evaluate the evidence for associations between *FTO* genotype (rs9939609 or a proxy) and macronutrients intake (total energy, total fats, saturated fatty acids (SFA), monounsaturated fatty acids (MUFA), polyunsaturated fatty acids (PUFA), carbohydrate and protein) in adults.

METHODS AND PROCEDURES

Our systematic review was conducted according to the Cochrane¹⁹ and the Centre for Reviews and Dissemination guidelines²⁰ and is reported in line with PRISMA guidelines²¹ (Supplementary material, Table 1). The protocol has been registered with PROSPERO, the International Prospective Register of Systematic Reviews (Registration number CRD42014010087).

Search strategy

Electronic searches were conducted to identify studies reporting the association between macronutrient intake (total energy, total fat, saturated, mono- and polyunsaturated fatty acids (SFA, MUFA, PUFA), carbohydrate and/or protein) and the *FTO* gene (rs9939609 or a proxy). The search strategy involved combining two search themes using the Boolean operator “and”. The first theme was (“*FTO*” OR “fat mass and obesity associated”) and the second theme was (“carbohydrate” OR “diet” OR “protein” OR “energy” OR “fat” OR “macronutrient”). OVID MEDLINE (<http://www.nlm.nih.gov/bsd/pmresources.html>), Embase (<http://www.embase.com/>), Scopus (www.scopus.com), and Cochrane (<http://www.thecochranelibrary.com/view/0/index.html>) were searched systematically for

studies published between inception and September 2014. Reference lists of identified publications and previously published related systematic reviews were hand searched to identify other studies potentially eligible for inclusion.

Study selection and screening

Observational studies, including cross-sectional, prospective and case-control studies and randomized trials evaluating the association between *FTO* and macronutrients intake were included in this review. Only English language abstracts were included. Studies in children and in animals were excluded. Two reviewers (KML and CCM) assessed titles and abstracts of all identified publications independently. When a study could not be excluded with certainty at this stage, the full-text was obtained for evaluation.

Data extraction and quality assessment

A standardized, pre-piloted form was used to extract data from the included studies for assessment of study quality and evidence synthesis. Data extraction and a validity assessment were carried out independently by two reviewers (KML, CCM) and any discrepancies were resolved by discussion with a third reviewer (JL). Data on participant characteristics (including ethnicity, age and sex), study designs, outcomes and exposures (*FTO* SNP and intakes of total energy, fat (including type of fat), carbohydrate and protein) were extracted. For the outcome data, the mean intakes or the beta coefficients for total energy (kcal/day) intake and intakes of fat, SFA, MUFA, PUFA, carbohydrate and protein (all expressed as percentage of total energy intake) per risk allele were extracted. Authors were

contacted to request missing/additional data. Cochrane Collaboration criteria were used to examine the risk of bias of each study, including completeness of outcome data and selective outcome reporting¹⁹. The *FTO* SNPs included in this meta-analyses have been reported to be in high linkage disequilibrium (LD)²².

Statistical analysis

Individual study beta coefficients were interrogated as the primary outcome for evaluation of per allele differences in macronutrients intake. In addition, where relevant data were available, energy and macronutrient intakes per kg body weight were calculated. Random-effects models were used to estimate the pooled effect sizes and account for both sampling error and inter-study population variation²³. Meta-estimates were weighed by the inverse of the variance of the effect size (that is, 1/variance), where variance took into account the two potential sources of variation (i.e. within-studies and between-studies variance). As suggested by Higgins *et al.*¹⁹ excessive weightings from “double counts” originating from the “shared” group (that is participants homozygous for the no risk allele) were controlled by splitting the sample size of the shared group into approximately equal smaller groups for the comparisons; the means and standard deviations were left unchanged. When available, we used results from multivariate models with the most complete adjustment for potential confounders as reported in the original studies. Additional subgroup analyses investigated variables including age, sex, ethnicity and BMI. All statistical analyses were conducted using Stata 13.0 software (Stata, College Station, TX, USA). The I^2 test was conducted to evaluate heterogeneity between studies²⁴ and the 95% CI for I^2 were calculated using Higgins *et al.*'s method^{25,26}. Publication bias was appraised by visual inspection of funnel plots of effect size

against the standard error, with asymmetry assessed formally with Begg's and Egger's tests, where a P-value < 0.1 was considered as significant²⁷. To investigate sources of heterogeneity, meta-regression was conducted using age (continuous), sex (binary), BMI (continuous), ethnicity (factor variable; African American, Asian, Spanish/Hispanic, Caucasian, Mixed) and study design (binary; intervention and observational) as covariates.

Sensitivity analyses

Stratified analyses were performed based on age group (binomial using the median age of participants in studies) and ethnicity (Caucasian, Asian, Spanish/Hispanic, African American or Mixed). To evaluate the validity of reported energy intake, basal metabolic rates were calculated by the Oxford equations²⁸ and used to estimate total energy intake to basal metabolic rate ratios (EI/BMR). Under-reporting of energy intake was considered evident for EI/BMR ratios of less than 1.55²⁹. To assess the influence of extreme values, studies where the beta coefficients for energy intake were $\pm 2SD$ from the mean were excluded.

Associations between *FTO* and total energy and macronutrients intake were adjusted for body weight in studies where these variables were available by risk allele. Galbraith plots were used as a secondary method of detecting between study heterogeneity. Where the data were available, we assessed the effect of alcohol intake on the relationship between *FTO* and total energy intake, the association between food energy (kcal/day) and *FTO* genotype and the association between percentage of total energy intake from alcohol and *FTO* genotype.

RESULTS

Our detailed searches identified 3 247 articles (Figure 1). After removal of duplicates a further 1 566 articles were excluded based on their titles and 58 full text articles were reviewed. Thirty two full-text articles were excluded due to insufficient information on dietary intakes and a further 7 as they were in children only. Fifty-six studies^{16-18,30-44} (from 26 full-text articles) were included in the meta-analysis (Table 1). Authors (n=25) were contacted for additional information, including body weight and percentage energy from alcohol, and those who provided additional information were acknowledged (n=16).

Study characteristics

Twenty-four studies used a population or community-based design. Six studies were cross-sectional in design, 11 were case-control or nested case-control studies, 8 were intervention studies and seven were family, twin or birth cohorts. The pooled population included in this meta-analysis was 213 173 adults. The mean age (\pm standard deviation) was 53.0 ± 9.6 years (range 31 to 75 years) and the mean BMI was 26.6 ± 2.45 kg/m² (range 19.4 to 36.3 kg/m²). Most studies used a Food Frequency Questionnaire (FFQ; n=40) to estimate dietary intakes, four used dietary recalls, 8 used food diaries and four used a combination of these tools. Ten studies comprised male only samples and three studies females only. Information on the numbers of males and females was unavailable in one study (Table 1).

Study quality and publication bias

No studies were excluded from the analyses based on quality assessment. Egger's regression test identified significant bias ($P=0.005$), whereas Begg's test did not ($P=0.273$).

FTO and macronutrient intake

The present meta-analysis demonstrated that for each copy of the *FTO* risk allele, adults had 6.46 kcal/day (95% CI: 10.76, 2.16; $P=0.003$) lower total energy intake (Figure 2). I^2 (95% CI) were as followings: Caucasian: 19.5% (0, 46); Asian: 38.7% (0, 70); Hispanic: 64.5% (0, 90); African American: 0% (0, 85); Mixed 0% (-). These findings remained significant after adjustment for body weight (-0.158 kcal/kg bodyweight/day [95% CI: -0.298, -0.017]; $P=0.028$). Adults carrying the *FTO* risk allele consumed 0.05% (0.005, 0.067; $P=0.028$) more total fat and 0.05% (0.014, 0.082; $P=0.006$) more protein (Table 2 and Supplementary Figures 1-3). Following adjustment for body weight the direction of these results changed: total fat (-0.003, [-0.006, -0.001]; $P=0.004$), carbohydrates (-0.002 [-0.004, -0.001]; $P=0.005$) and protein (-0.002 [-0.003, -0.001]; $P=0.001$). All results were characterised by low levels of heterogeneity. No significant associations between *FTO* genotype and intakes of SFA, MUFA or PUFA were observed but this finding is based on 6 studies only.

Meta-regression analysis

Univariate meta-regression analysis indicated that total energy intake (kcal/day) was 62.0 kcal/day lower in Caucasian individuals (95% CI, 106.8, 17.3; $P=0.008$), 49.6 kcal/day lower Asian individuals (95% CI, 95.5, 3.7; $P=0.035$) and 67.5 kcal/day lower in Spanish/Hispanic individuals (95% CI, 116.4, 18.5; $P=0.008$) when compared with individuals of mixed

ethnicities. Protein intake (% energy) was 0.14% (95% CI, 0.082, 0.193; $P<0.001$) higher in intervention studies compared with observational studies. No relationships were observed between intakes of protein (% energy) and age, sex, BMI or sample size, nor between total energy (kcal/day) or fat, SFA, MUFA, PUFA or carbohydrate (expressed as % total energy) intake and age, sex, ethnicity, BMI, study design or sample size.

Sensitivity and subgroup analyses

Stratified analyses (Table 2) indicated that total energy intake was higher in carriers of the risk allele among Caucasian individuals only, and not in other ethnic groups but this effect was evaluated by rather few studies ($n=16$). With each copy of the *FTO* risk allele, energy intakes were lower in population-based cohorts and intervention studies only. In contrast, total energy intakes were higher per copy of the risk allele in case-control and nested case-control studies. The inverse relationship between energy intake and *FTO* genotype was significant in overweight individuals only, and not in normal weight or obese individuals.

To estimate potential under-reporting of energy intakes, EI/BMR ratios were calculated where relevant data were available ($n=16$). This showed that EI/BMR ratios were not significantly different across risk alleles (two copies of the risk allele, 1.30 ± 0.31 ; one copy, 1.33 ± 0.29 ; no copies, 1.23 ± 0.31 ; $P=0.635$).

To assess the influence of extreme values reported for beta coefficients of per allele energy intake, studies with beta coefficients more than $\pm 2SD$ from the mean were excluded ($n=3$).

Exclusion of these studies resulted in a slightly larger estimate of reduced total energy

intake (6.6 kcal/day, 95% CI 10.7, 2.4, $P=0.002$; Supplementary Figure 4) in those carrying the risk variant of *FTO*.

Galbraith plots were used as an additional method of detecting heterogeneity between studies. Of the 56 studies included, these analyses identified one study (NHLBI Family Heart Study) where the effect size fell outside of the 95% limits (ratio of effect size to standard error: -2.3; Supplementary Table 2) and was therefore identified as contributing to heterogeneity⁴⁵. Exclusion of this study did not change the significance of the results but lowered the point estimate for reduction in energy intake in those carrying the *FTO* risk allele (-5.8 kcal/day, 95% CI: -10.0, -1.6; $P=0.007$). I^2 (95% CI) were as followings: Caucasian: 13.5% (0, 42); Asian: 38.7% (0, 70); Hispanic: 64.5% (0, 90); African American: 0% (0, 85); Mixed 0% (-). Finally, small but significant, positive associations were observed between carriage of the *FTO* risk allele and BMI as well as with body mass. Individuals with two copies of the *FTO* risk allele had a 0.16kg/m² (95% CI: 0.068, 0.257; $P=0.001$) higher BMI and weighed 0.17kg (95% CI: 0.119, 0.227; $P<0.001$) more than individuals with no copies of the *FTO* risk allele (data from 19 studies).

The effect of alcohol intake was assessed across *FTO* risk allele groups by investigating the effect of food energy in 13 studies and the effect of percentage total energy intake from alcohol in 11 studies. Individuals consumed 0.004% (95% CI: -0.032, 0.039) more energy from alcohol per copy of the *FTO* risk allele but this effect was not significant ($P=0.840$; Table 2). After excluding the contribution of alcohol to total energy intake, i.e. considering dietary energy intakes only, results showed that with each copy of the *FTO* risk allele, individuals consumed 6.4 kcal/day (95% CI: -15.6, 2.7) less energy and, with the wider

confidence intervals, this effect did not reach significance ($P=0.169$; Supplementary Figure 5).

DISCUSSION

Main findings

To our knowledge, this is the first systematic review and meta-analysis to investigate associations between *FTO* genotype and macronutrients intake in adults. The present meta-analysis of 56 studies, involving 213 173 individuals, demonstrated that for each copy of the *FTO* risk allele, individuals reported significantly lower energy intake (mean 6.5 kcal/day). Although this difference is small, it is statistically significant and it is in the opposite direction to that expected from the conventional assumption that the higher body masses in those carrying the *FTO* risk variant are due to greater energy intakes. However, the latter relationship was evident in Caucasians only (there are too few studies in other ethnic groups at present) and overweight individuals. In addition, Galbraith plots indicated that one study (FamHS) was identified as an outlier, after removal of this study, the relationship between *FTO* genotype and energy intake remained significant ($P=0.007$). Our analysis also suggested that *FTO* genotype is associated with small but statistically significant changes in sources of dietary energy intake; those carrying the *FTO* risk allele consumed significantly higher proportions of dietary energy from fat and protein.

Comparisons with other studies

Our finding of a small but significantly lower energy intake among *FTO* carriers is in line with a recent meta-analysis of individual level data in adults only; Qi *et al.*¹⁸ reported that carriers

of the *FTO* risk allele consumed less total energy (6.4 [95% CI -10.1, -2.6] kcal/day) and a higher protein intake (0.08 [0.06, 0.10]% total energy, $P < 0.001$). Here we have evaluated the impact of dietary misreporting which, due to self-reporting bias, is a pervasive problem in most dietary studies and is often more pronounced in overweight and obese individuals⁴⁶. Thus, if there was differential misreporting of dietary energy intake according to *FTO* genotype e.g. because of the higher prevalence of obesity in those carrying the risk allele, or for other reasons, such bias could make conclusions about genotypic effects on energy intake equivocal. Recent evidence suggests that the *FTO* risk allele may be associated with cognitive decline in 45-64 year olds⁴⁷, particularly with a decline in verbal memory among Caucasians. These findings would provide a mechanism for potentially greater unintentional dietary misreporting among *FTO* allele carriers when assessing dietary intake using recall methods such as those commonly employed in the studies we reviewed. To date, the evidence in this area is limited. Sonestedt *et al.*⁴⁸ investigated the role of dietary misreporting in the relationship between carriage of the *FTO* allele and energy intake. The authors used information on physical activity, basal metabolic rates and energy intakes to predict dietary misreporting. Having excluded both under- and over-reporters of energy intake, Sonestedt *et al.*⁴⁸ found that the inverse relationship between *FTO* risk allele and energy intake was no longer significant. Furthermore, Sonestedt *et al.*⁴⁸ reported that in individuals with a BMI $> 30 \text{ kg/m}^2$, there was no significant difference between *FTO* genotypes in the number of under-reporters. Furthermore, exclusion of under-reporters did not affect the positive relationship between carriage of the *FTO* risk allele and intakes of protein and fat⁴⁸, all of which are in line with our findings. Previous evidence suggests that the magnitude of energy under-reported is 20-45%^{49,50}. Our counter-intuitive finding of lower reported energy intakes among subjects carrying the *FTO* risk allele is unlikely to be

explained by systematic under-reporting by carriers of the risk allele of *FTO* (rs9939609) because estimates of EI/BMRs were very similar for those carrying 0, 1 and 2 copies of the *FTO* risk allele. However, in the absence of reliable estimates of energy expenditure or of individual level data for age, sex and body mass (required for prediction of individual dietary energy needs), it is difficult to exclude the possibility that the small differences in energy intake observed in the studies considered in our systematic review are due to energy under-reporting by carriers of *FTO* risk allele. Alternatively, as shown in overfeeding studies⁵¹, the *FTO* risk variant may lead to a higher energy efficiency in weight gain per kcal intake, which is a mechanism that requires further investigation.

For many adults, alcohol contributes substantially (3 – 9%) to total energy intake and may drive higher food intake⁵². Thus, genetic differences in actual or reported alcohol intake could confound apparent differences in energy and macronutrients intake according to *FTO* genotype. Our meta-analysis was based primarily on reported total energy intakes rather than energy intakes from food only. There may be a positive relationship between the *FTO* genotype and alcohol intake⁵³, although this finding is not consistent⁵⁴. Previous evidence syntheses have not investigated the potential impact of alcohol intake on the relationship between *FTO* genotype and energy intake¹⁸. Where relevant data were available, we assessed the relationship between intake of food energy and *FTO* genotype, thereby excluding any influence of alcohol intakes on the analyses. Moreover, where relevant data were available, we estimated the percentage energy intake from alcohol to investigate possible differences between *FTO* genotypes. These exploratory analyses, based on a limited number of relevant studies, suggest that the lower intake of energy per copy of *FTO* variant was not affected by alcohol intake and that alcohol intake is not significantly

different between *FTO* risk alleles. However, as with energy intake, under-reporting of alcohol intake, is a pervasive issue⁵⁵.

Although animal studies suggest that *FTO* expression may affect energy homeostasis via changes in food intake^{9,56}, our findings provide little support for the hypothesis that increased energy intake mediates the obesogenic effects of the *FTO* risk allele in humans. Due to limited data on physical activity in these studies, we were unable to assess the effect of *FTO* on energy expenditure. Nonetheless, research using doubly labelled water suggests that there is no difference in energy expenditure between *FTO* risk variants after adjustment for body weight¹⁴. Furthermore, there is no evidence for a direct connection between obesity-associated variants and *FTO* expression^{57,58}. Smemo *et al.*⁵⁹ demonstrated recently that these obesogenic SNPs within *FTO* may be regulated by the homobox gene *IRX3*, referred to as the “functional obesity gene”. The reduction in body weight of 25-30% in *IRX3*-deficient mice was more pronounced when animals were subjected to a high-fat diet, thereby supporting the potential for *FTO* to influence energy efficiency, and suggesting that *IRX3* may be the pivotal link between *FTO*, macronutrient intake and obesity⁵⁹. Furthermore, an additional SNP in the first intron of *FTO*, *RPGRIP1L*, has been proposed as partly or exclusively responsible for the obesity susceptibility signal at the *FTO* locus in mice⁶⁰.

Strengths and limitations

The strengths of this study include application of a rigorous methodology in the systematic review of the literature and the availability of data from a large population of 213 173 individuals. In addition, we examined the potential confounding effect of alcohol intake (a significant source of energy for many adults) on the relationship between *FTO* genotype and

energy intake. A limitation of the present study was that sensitivity analyses using intakes of food energy and data on body weight were possible for less than half of the studies included. This limited our ability to ascertain whether our findings were attenuated following these adjustments. Furthermore, all studies utilised self-report methods for quantifying dietary intakes. The well-recognised limitations of dietary self-reporting tools may also be amplified when focusing on overweight and obese subjects. Progress in the development of objective biomarkers of dietary intake may overcome some of these limitations⁶¹. Finally, the findings of this review are based largely on studies of Caucasians, thus highlighting the lack of studies that have assessed associations between *FTO* genotype and dietary intake among non-Caucasians.

Implications of the findings and future research

Despite observing significant differences in energy and nutrient intakes between *FTO* variants, these seem to be too small to play an important role in the greater obesity prevalence commonly seen among *FTO* carriers. In addition, given the growing interest in the development of personalised advice based on the genetic makeup of individuals, the findings from this study indicate that there is limited justification for providing differential advice for total energy and macronutrients intakes according to *FTO* genotype as a means of combatting the obesity epidemic.

This review indicates there is a paucity of studies evaluating the association of *FTO* and dietary intakes among non-Caucasian ethnic groups. This situation is expected to change given the great interest on the development of personalised lifestyle advice as an approach to addressing the obesity epidemic. Dietary misreporting, a ubiquitous problem in most

395 dietary studies, was identified in the reviewed studies. Assessment of dietary intake is often
396 considered a straightforward task, receiving little attention during the design of studies, but
397 it is now clear that inaccuracies in the measurement of dietary intake may lead to spurious
398 associations between diet and health. Therefore, future research should aim to develop and
399 use more accurate methods of assessing dietary intake and energy balance⁶¹.

400 Recent research on dietary patterns suggests a relationship between greater consumption
401 of fried food and *FTO* genotype⁶². These results are in line with our findings of small but
402 significantly greater intakes of dietary fat and protein by *FTO* carriers, which may be
403 attributable to the consumption of high-fat, processed meat products. However, given the
404 findings of energy under-reporting across all studies and *FTO* groups, it is uncertain whether
405 there is selective under-reporting of dietary fat intake⁶³. With the growing emphasis on
406 whole foods and dietary patterns in dietary recommendations, there may be future scope
407 for genetics-based dietary advice targeting dietary patterns.

408 Finally, as summarised in Table S3, the present systematic review and meta-analysis has
409 highlighted a number of areas which should be improved in future studies. When reporting
410 dietary intakes, total energy intakes (kcal/day) and macronutrients intakes should be
411 reported for each copy of the risk allele. Critically, if dietary intakes are self-reported,
412 estimates of dietary misreporting based on the ratio of BMR to energy intake should be
413 reported per copy of the risk allele. Without this information it is not possible to assess
414 objectively the role of dietary intake in mediating the effects of genetic risk of obesity.
415 Finally, it is recommended that studies provide per risk allele data on physical activity
416 (quantified as Metabolic Equivalents of Task (METs)). This information, together with
417 quantitative information on dietary intakes and estimated BMRs, would help to provide

insight into which aspect(s) of the energy balance equation is influenced by the genetic variant.

Conclusions

Our systematic review and meta-analysis indicates a weak inverse association between the *FTO* risk allele and energy intake in adults, which is consistent with recent findings from a meta-analysis of individual level data¹⁸. Our findings also suggest a role of *FTO* in altering the proportions of dietary energy consumed as fat and protein. With the lack of appropriate individual data, we could not discount the possibility that dietary intake misreporting is responsible for these apparent effects. Furthermore, with limited data on energy expenditure via physical activity, we were unable to ascertain the effects of the *FTO* risk allele on the energy balance equation. Future intervention and mechanistic studies in humans, where dietary intakes are recorded objectively and the mechanisms of the action of *FTO* and its associated genes are investigated, are required to better understand the putative relationship between *FTO* and macronutrients intake.

Fig 1. Study selection flow diagram based on the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-analyses) statement

Fig 2. Forest plot of associations between *FTO* rs9939609 genotype or a proxy and total energy intake in a random effects meta-analysis of 213 173 adults. Studies are stratified by ethnic background and sorted by sample size (smallest to largest). The effect size (ES) represents the beta coefficient for the difference in energy intake (kcal/day) per minor allele of *FTO* rs9939609 or a proxy.

*KM Livingstone, CM Celis & JC Mathers on behalf of Food4Me – unpublished data, ** Basal metabolic rates (BMR) were calculated using Oxford equations²⁸ and ratios were estimated by dividing reported energy intakes by BMRs

Table S2 Galbraith plot values sorted by decreasing beta/SE. Detection of studies acting as sources of heterogeneity for the associations between FTO rs9939609 genotype (or a proxy) and total energy intake (kcal/day). Study 55 is an outlier as the effect size lies outside the 95% confidence interval for the pooled effect.

Table S3. Recommendations for future studies into genotype/dietary relationships

Topic	Recommendation
Per risk allele breakdown	Provide data stratified by each copy of the risk allele. These data should include demographic characteristics (sample size, age, sex, height, weight, BMI), dietary intakes (total energy and macronutrients intake and degree of misreporting) and lifestyle variables (physical activity)
Dietary intakes	Report total energy intakes (kcal/day or KJ/day) and percentage energy intakes from total fat, carbohydrates, protein and alcohol. If available, the inclusion of the percentage energy intakes from saturated, mono- and polyunsaturated fat and sugar is encouraged.
Dietary misreporting	If dietary intakes are self-reported, provide individual-level basal metabolic rates (BMR) and the ratios of BMR to total energy intake, as an estimation of dietary under-reporting.
Physical activity	Report levels of physical activity in MET (metabolic equivalent)

Table S3. PRISMA checklist

Section/topic	#	Checklist item	Reported on page #
TITLE			
Title	1	Identify the report as a systematic review, meta-analysis, or both.	1
ABSTRACT			
Structured summary	2	Provide a structured summary including, as applicable: background; objectives; data sources; study eligibility criteria, participants, and interventions; study appraisal and synthesis methods; results; limitations; conclusions and implications of key findings; systematic review registration number.	4
INTRODUCTION			
Rationale	3	Describe the rationale for the review in the context of what is already known.	6
Objectives	4	Provide an explicit statement of questions being addressed with reference to participants, interventions, comparisons, outcomes, and study design (PICOS).	7
METHODS			
Protocol and registration	5	Indicate if a review protocol exists, if and where it can be accessed (e.g., Web address), and, if available, provide registration information including registration number.	7
Eligibility criteria	6	Specify study characteristics (e.g., PICOS, length of follow-up) and report characteristics (e.g., years considered, language, publication status) used as criteria for eligibility, giving rationale.	7-8
Information sources	7	Describe all information sources (e.g., databases with dates of coverage, contact with study authors to identify additional studies) in the search and date last searched.	7-8
Search	8	Present full electronic search strategy for at least one database, including any limits used, such that it could be repeated.	7-8
Study selection	9	State the process for selecting studies (i.e., screening, eligibility, included in systematic review, and, if applicable, included in the meta-analysis).	7-8
Data collection process	10	Describe method of data extraction from reports (e.g., piloted forms, independently, in duplicate) and any processes for obtaining and confirming data from investigators.	8-9
Data items	11	List and define all variables for which data were sought (e.g., PICOS, funding sources) and any assumptions and simplifications made.	8-9

Table S3. PRISMA checklist continued

Section/topic	#	Checklist item	Reported on page #
Risk of bias in individual studies	12	Describe methods used for assessing risk of bias of individual studies (including specification of whether this was done at the study or outcome level), and how this information is to be used in any data synthesis.	9
Summary measures	13	State the principal summary measures (e.g., risk ratio, difference in means).	9
Synthesis of results	14	Describe the methods of handling data and combining results of studies, if done, including measures of consistency (e.g., I^2) for each meta-analysis.	9
Risk of bias across studies	15	Specify any assessment of risk of bias that may affect the cumulative evidence (e.g., publication bias, selective reporting within studies).	9
Additional analyses	16	Describe methods of additional analyses (e.g., sensitivity or subgroup analyses, meta-regression), if done, indicating which were pre-specified.	10
RESULTS			
Study selection	17	Give numbers of studies screened, assessed for eligibility, and included in the review, with reasons for exclusions at each stage, ideally with a flow diagram.	10-11
Study characteristics	18	For each study, present characteristics for which data were extracted (e.g., study size, PICOS, follow-up period) and provide the citations.	11
Risk of bias within studies	19	Present data on risk of bias of each study and, if available, any outcome level assessment (see item 12).	11-12
Results of individual studies	20	For all outcomes considered (benefits or harms), present, for each study: (a) simple summary data for each intervention group (b) effect estimates and confidence intervals, ideally with a forest plot.	12-15
Synthesis of results	21	Present results of each meta-analysis done, including confidence intervals and measures of consistency.	Tables/Figures/Suppl
Risk of bias across studies	22	Present results of any assessment of risk of bias across studies (see Item 15).	12-15
Additional analysis	23	Give results of additional analyses, if done (e.g., sensitivity or subgroup analyses, meta-regression [see Item 16]).	12-15

Table S3. PRISMA checklist continued

Section/topic	#	Checklist item	Reported on page #
DISCUSSION			
Summary of evidence	24	Summarize the main findings including the strength of evidence for each main outcome; consider their relevance to key groups (e.g., healthcare providers, users, and policy makers).	15-19
Limitations	25	Discuss limitations at study and outcome level (e.g., risk of bias), and at review-level (e.g., incomplete retrieval of identified research, reporting bias).	19
Conclusions	26	Provide a general interpretation of the results in the context of other evidence, and implications for future research.	20-21
FUNDING			
Funding	27	Describe sources of funding for the systematic review and other support (e.g., supply of data); role of funders for the systematic review.	2
